Solution to Ex. 1

Make use of the fact that death and aging shocks are memoryless within an age class.

The remaining life expectancy of the last age class $\Theta(A)$ in analogy to the Blanchard model is

$$
\Theta^A = \gamma^A / (1 - \gamma^A). \tag{1.1}
$$

Then we work backwards and express conditional life expectancy recursively as

$$
\Theta^a = \frac{\gamma^a \omega^a + (1 - \omega^a)\gamma^a (\Theta^{a+1} + 1)}{1 - \gamma^a \omega^a}.
$$
 (1.2)

Life expectancy at birth is equal to Θ^1 .

Show: Some simulations using the code simlifeexpect.

Taxation at the intensive and the extensive margin

Recall the two conditions for the intensive margin (ℓ) and extensive margin (δ)

$$
\delta_t: \quad \left[(1-\tau_t^W) w_t \ell_t \theta_t - b_t \right] / pc_t - \varphi(\ell_t) = \underline{h}_t
$$

$$
\ell_t: \varphi'(\ell_t) \cdot pc_t = (1 - \tau_t^W) w_t \theta_t
$$

The government instruments τ^W , b and τ^C distort these decisions. A way to summarize the total distortion \Rightarrow effective tax rates.

K ロ) - K (D) > K (E) > K (E) > 1 (E) -

Effective taxe rates

The total distortion at a margin can be summarized by a single effective tax rate.

The intensive margin:

$$
\varphi'(\ell_t) = (1 - \hat{\tau}_t^W) w_t \theta_t, \quad \hat{\tau}_t^W = \frac{\tau_t^C + \tau_t^W}{1 + \tau_t^C}
$$

The extensive margin (participation tax):

$$
(1-\hat{\tau}_t^{\delta})w_t\ell_t\theta_t - \varphi(\ell_t) = \underline{h}_t, \quad \hat{\tau}_t^{\delta} = \frac{\tau_t^C + \tau_t^W + b_t/(w_t\ell_t\theta_t)}{1+\tau_t^C}.
$$

K ロ ▶ K @ ▶ K 할 ▶ K 할 ▶ ... 할 ... ⊙ Q Q ^

Average vs. marginal tax rates

So far we assumed a **linear tax schedule**, e.g. tax liability is $\tau^W\cdot w\ell\theta.$ But what if this is not the case?

Assume as a **generalization** that the tax liability is $T(w\ell\theta)$. Then the two labor supply optimality conditions are:

$$
\delta_t: \quad \left[\left(1 - \frac{\mathcal{T}^W(w_t \ell_t \theta_t)}{w_t \ell_t \theta_t} \right) \cdot w_t \ell_t \theta_t - b_t \right] / pc_t - \varphi(\ell_t) = \underline{h}_t
$$

$$
\ell_t: \varphi'(\ell_t) \cdot pc_t = \left(1 - \mathcal{T}^{W\prime}(w_t \ell_t \theta_t)\right) \cdot w_t \theta_t
$$

where $\frac{\mathcal{T}^{W}(w_t\ell_t\theta_t)}{w_t\ell_t\theta_t}$ $\frac{V(w_t\ell_t\theta_t)}{w_t\ell_t\theta_t}$ is the average tax rate and $\mathcal{T}^{W\prime}(w_t\ell_t\theta_t)$ is the marginal tax rate. In case of a linear tax schedule, i.e. $T^{W}(w \ell \theta) = \tau^{W} \cdot w \ell \theta$ both are equal to τ^{W} .

KID KAR KERKER E 1990

Measures of progressivity

Definition (Progressive taxation)

First, define earnings $e = w \ell \theta$. A tax schedule $\mathcal{T}^W(e)$ is progressive (regressive) iff the average tax rate is increasing (decreasing) in income e.

As $d(T^W(e)/(e))/de = \frac{T^{W}(e) - T^W(e)/e}{e}$ $\frac{e^{i} - 1}{e}$ it is clear that if a schedule is progressive (regressive) the marginal rate will exceed (fall short of) the average rate, i.e. $\mathcal{T}^{W \prime} (e) > ($ $\mathcal{T}^{W} (e) / e$.

Two measures of local progressivity:

 \triangleright Coefficient of tax liability progression: defined as elasticity of T w.r.t. e, i.e.

$$
\varepsilon = \frac{d\mathcal{T}^W}{de\ \mathcal{T}^W} = \frac{\text{marg. rate}}{\text{aver. rate}}.
$$
 (2.1)

 \triangleright Coefficient of residual income progression: defined as elasticity of $e - T$ w.r.t. e, i.e.

$$
\eta = \frac{de - T^{W}}{de} \frac{e}{e - T^{W}} = \frac{1 - \text{marg. rate}}{1 - \text{aver. rate}}. \tag{2.2}
$$

[Walras' Law](#page-14-0)

イロト イ部 トイモト イモト 一毛

Detrending $(1/3)$

In our framework we usually use **exogenous growth of labor productivity** by rate g implying a growth factor $G = 1 + g$.

Denote the **level of technological progress** as X then the current level is

$$
X_t = G^t X_0. \tag{3.1}
$$

 $\mathbf{E} = \mathbf{A} \oplus \mathbf{B} + \mathbf{A$

In a **balanced growth setting** all variables of the economy (output, capital stock, consumption, investment, \ldots) grow at rate g we therefore want to detrend by this growth to retain the characteristic of an equilibrium where all variables are constant.

Detrending (2/3)

How does detrending work?

Denote non-detrended variables using a tilde, e.g. \tilde{K}_t . Then the detrended capital stock is

$$
K_t = \tilde{K}_t / X_t \quad \Rightarrow \quad \tilde{K}_t = X_t K_t \tag{3.2}
$$

We simply use this definition in all our equations, e.g. for the law of capital and the consumption function

$$
\tilde{K}_{t+1} = (1 - \delta^{\mathcal{K}}) \tilde{K}_t + \tilde{I}_t \quad \Leftrightarrow \quad G K_{t+1} = (1 - \delta^{\mathcal{K}}) K_t + I_t. \tag{3.3}
$$

$$
\tilde{C}_t = (\Omega_t)^{-1} (\tilde{A}_t + \tilde{H}_t) \Rightarrow C_t = (\Omega_t)^{-1} (A_t + H_t)
$$
 (3.4)

Hence, in **linear difference equations** G will pop up.

KORK REPARE PROVIDE

Detrending (3/3)

How to proceed for **non-linear** difference equations, e.g. indirect utility with non-linear felicity, for example $u(x) = x^{\rho}$?

$$
U_t = u(\tilde{C}_t) + \beta U_{t+1}, \quad \Rightarrow \quad U_t = u(X_t C_t) + \beta U_{t+1}. \tag{3.5}
$$

Observe that $u(X_t C_t) = (X_t)^\rho (C_t)^\rho$, $u(X_{t+1} C_{t+1}) = (X_t G)^\rho (C_{t+1})^\rho$, etc. Hence, doing a **positive monotone transformation** $V_t = U_t/(X_t)^\rho$ results in the for the maximization problem equivalent expression

$$
V_t = u(C_t) + \beta G^{\rho} V_{t+1}.
$$
\n(3.6)

Despite detrending, $g > 0$ has real effects (on **effective discounting**), e.g. for human wealth (here for the Ramsey model)

$$
H_t = y_t + \frac{GH_{t+1}}{R_{t+1}} \quad \text{in st.st.} \quad H = y \cdot \frac{1+r}{r-g}.\tag{3.7}
$$

[Mixture of anticipated and unanticipated shocks](#page-12-0)

[Walras' Law](#page-14-0)

Mixture of anticipated and unanticipated shocks

In principle agents learn about a reform in $t = 1$.

Problem: How to simulate two reforms becoming effective at t_1 and $t_2 > t_1$, when agents **cannot anticipate** the second reform and learn about it only in t_2 ?

We discuss code implementations: Blanchard unanticipated.

Possible applications: Introduction of a pension reform during the ongoing demographic transition.

Walras' Law

Good modeling discipline: Always check Walras' Law which has to hold even outside of equilibrium.

Define the following excess demands

$$
\begin{aligned}\n\text{assets}: \qquad & \zeta_t^A = V_t + D_t^F + D_t^G - A_t \\
\text{labor}: \qquad & \zeta_t^L = L_t^D - L_t^S \\
\text{goods}: \qquad & \zeta_t^Y = C_t + I_t + J_t + C_t^G + TB_t - Y_t \\
\text{government}: \qquad & \zeta_t^G = Rev_t - Exp_t - PB_t\n\end{aligned}
$$

Then Walras' Law is (proof in script)

$$
\zeta_t^Y + w_t \zeta_t^L + \zeta_t^A + \zeta_t^G - \frac{G\zeta_{t+1}^A}{R_{t+1}} = 0.
$$

Discuss in code Blanchard government.
